Summary

Although protists are critical components of marine ecosystems, they are still poorly characterized. Here we analysed the taxonomic diversity of planktonic and benthic protist communities collected in six distant European coastal sites. Environmental deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) from three size fractions (pico-, nano- and micro/mesoplankton), as well as from dissolved DNA and surface sediments were used as templates for tag pyrosequencing of the V4 region of the 18S ribosomal DNA. Beta-diversity analyses split the protist community structure into three main clusters: picoplankton-nanoplankton-dissolved DNA, micro/ mesoplankton and sediments. Within each cluster, protist communities from the same site and time clustered together, while communities from the same site but different seasons were unrelated. Both DNA and RNA-based surveys provided similar relative abundances for most class-level taxonomic groups. Yet, particular groups were overrepresented in one of the two templates, such as marine alveolates (MALV)-I and MALV-II that were much more abundant in DNA surveys. Overall, the groups displaying the highest relative contribution were Dinophyceae, Diatomea, Ciliophora and Acantharia. Also, well represented were Mamiellophyceae, Cryptomonadales, marine alveolates and marine stramenopiles in the picoplankton, and Monadofilosa and basal Fungi in sediments. Our extensive and systematic sequencing of geographically separated sites provides the most comprehensive molecular description of coastal marine protist diversity to date.

Introduction

Protists or unicellular eukaryotes cover a wide spectrum of cell sizes, shapes and taxonomic affiliations (Schaechter, 2012). They represent the majority of eukaryotic lineages, so studying their diversity is of primary interest for understanding the eukaryotic tree of life (Keeling et al., 2005; Burki, 2014). Moreover, protists play a variety of crucial roles in marine ecosystems from primary producers, predators, decomposers to parasites (Sherr et al., 2007), leading to much effort in quantifying particular species and inferring their ecological functions. A vast literature exists in which species of dinoflagellates (e.g. Graham et al., 2004), diatoms (e.g. Olguín et al., 2006) and ciliates (e.g. Dolan et al., 2013) have been studied based on morphological features observable in light microscopy, a task that requires considerable expertise and time to key out species accurately. Even for these relatively visible groups, examples are known of morphologically similar individuals belonging to different cryptic species (Amato et al., 2007) or morphologically distinct types from the same species (Pizay et al., 2009). Accurate identification may thus not always be discerned from cell morphology alone, and this is more critical for protists below 20 µm in size that often lack conspicuous shapes (Massana, 2011). Over the last decades, deoxyribonucleic acid (DNA) sequencing of environmental phylogenetic markers has changed our perception of microbial diversity in most ecosystems. These molecular surveys have been instrumental in decoding the large protist diversity and in unveiling new lineages, such as Picozoa (Not et al., 2007; Seenivasan et al., 2013), marine alveolates (MALV) clades (Guillou et al., 2008) and marine stramenopiles (MAST) clades (Massana et al., 2004; 2014).

Earlier molecular surveys were based on clone libraries of near full-length 18S ribosomal (r)DNA genes followed by Sanger sequencing of a subset of the clones (Díez et al., 2001; López-García et al., 2001; Moon-van der Staay et al., 2001). The resulting high-quality, often manually checked environmental sequences have been crucial for the phylogenetic placement of novel clades and, together with sequences from monoclonal cultures, are the basis of reference rDNA databases (Guillou et al., 2013; Pernice et al., 2013). However, traditional clone libraries only capture the most dominant species in the community (Pedrós-Alió, 2006), a limitation bypassed by high-throughput sequencing (HTS) methods. By providing the deep inventories needed both for taxonomic descriptions and sample comparisons, HTS has enabled microbial ecology to advance greatly. High-throughput sequencing has been applied to study protist diversity in a wide variety of systems, including surface and deep marine waters (Amaral-Zettler et al., 2009; Cheung et al.,

2010; Edgcomb *et al.*, 2011; de Vargas *et al.*, 2015), marine sediments (Bik *et al.*, 2012), lakes (Mangot *et al.*, 2013), soils (Bates *et al.*, 2013) and metazoan hosts (He *et al.*, 2014). In the case of marine protists, most studies have targeted a specific size fraction or a particular location. In addition, these surveys generally used environmental DNA as template for polymerase chain reaction (PCR) amplification, and it has been shown that using RNA extracts instead can provide a different picture of biodiversity (Stoeck *et al.*, 2007; Not *et al.*, 2009; Lejzerowicz *et al.*, 2013) and useful complementary information (Blazewicz *et al.*, 2013).

The present study is an investigation of benthic-pelagic protists in marine habitats along the European coastline, sampled between 2009 and 2010 during the research program BioMarKs. The 95 different pyrosequenced samples analysed herein address total protist diversity from benthic and planktonic (size-fractionated) communities using an eukaryotic 'universal' primer set to PCR amplify the V4 rDNA pre-barcode (Pawlowski et al., 2012) from both DNA and RNA extracts. Previous studies using this sequencing dataset focused on particular taxonomic groups, such as uncultured MAST (Logares et al., 2012), cercozoan amoebae (Berney et al., 2013) or diatoms (Nanjappa et al., 2014). More recently, we used a subset of the samples (23 planktonic RNA samples) and newly collected HTS reads (Illumina sequencing of the V9 18S rDNA region) to investigate the patterns of a particular community property, the rare biosphere (Logares et al., 2014). Here, we analyse the complete 454 dataset from a taxonomic community perspective to address the following questions: How different are the protist communities found in the pico-, nano-, micro/mesoplankton and sediments? Does the dissolved DNA fraction originate from particular taxonomic groups and/or organismal size fractions? Do DNA and RNA surveys provide similar protist diversity profiles? Which taxonomic groups are differentially represented in either survey? Which groups dominate in each plankton organismal size fraction and associated sediments? Overall, our study highlights fundamental questions on the diversity of protists, an important but less known component of marine microbial ecosystems (Caron et al., 2009).

Results

As a product of the joint effort within the BioMarKs project, we sampled six European coastal sites in the water column and sediments (Table 1). The thirteen planktonic communities were size fractionated (pico-, nano-, micro/ mesoplankton and dissolved DNA) and, together with seven benthic communities, used to obtain environmental DNA and RNA for pyrosequencing the V4 region of the 18S rDNA. Most assayed templates were successful, and

Table 1. Coastal marine sites visited and water column (surface and DCM) and sediment samples taken for investigating global protist diversity by pyrosequencing. Each planktonic community is analysed in up to seven 454 samples (pico, nano and micro/mesoplankton by RNA/DNA plus dissolved DNA) and each sediment sample in two (by RNA/DNA). Cases with no sequencing results are noted. See Table S1 for details on the number of pyrotags for each 454 sample.

a. No results for micro/mesoplankton RNA.

we obtained 26 pyrosequenced samples for picoplankton, 26 for nanoplankton, 21 for micro/mesoplankton, eight for dissolved DNA and 14 for sediments (Table 1). The pyrotag number for each 454 sample is detailed in Table S1 (~9000 pyrotags per sample on average). Pyrotags from these 95 samples clustered in 15 295 OTU₉₇ (Table S2), which were classified into 99 eukaryotic taxonomic groups (excluding unknown, metazoan and nucleomorphs). The broad coverage of this dataset across ecological and taxonomic scales provided a unique opportunity to study the diversity of both planktonic and benthic marine coastal protists.

Reproducibility of PCR and 454 reactions at the operational taxonomic unit level

We explored the reproducibility of sequencing outputs using a subset of nucleic acid extracts (11 DNA and 14 RNA) derived from three cruises (two from Blanes, 11 from Naples 2009 and 12 from Oslo 2009) and including the four compartments (eight picoplankton, seven nanoplankton, five micro/mesoplankton and five sediments). Each duplicated pair (same nucleic acid template and separate PCR and 454 reactions) was selected from the operational taxonomic unit (OTU) table of 120 samples (Table S2), and linear regressions were performed by plotting OTU abundances in each pair. The pyrotag ratio between duplicates ranged from ~1 to 0.05 and was used to display the statistics of all regressions at once (Fig. 1). The R² coefficients (Fig. 1A) were always high (0.89 on average) and independent of pyrotag ratios. This indicated that the same abundant OTUs were found at similar relative abundances in duplicates. The regression slopes were explained by pyrotag ratios (R² of 0.92; slope of 0.84; P < 0.001), indicating that OTU abundances increased proportionally with the number of pyrotags in the sample. Next, we explored the pyrotags and OTUs shared between duplicates and calculated the shared percentages of the pair with fewer pyrotags (Fig. 1B). The amount of shared OTUs ranged from 32% to 89% and was higher at low pyrotag ratios, displaying a significant relationship ($R^2 = 0.52$, P < 0.001). Indeed, it was easier to find OTUs from the sample with less pyrotags in its duplicate with higher sequencing effort. The percentage of pyrotags included in the set of shared OTUs was always high (average of 91%), and its variation was poorly related to pyrotag ratios (P = 0.048), indicating that OTUs appearing in only one duplicate contained few pyrotags. Thus, as expected, most differences between duplicates are found among the rare OTUs.

Comparisons between communities

Beta-diversity patterns of protist assemblages were explored in a dendrogram with 92 samples. Structuring patterns revealed three main groups of samples: (i)

regression line shown) and percentage of pyrotags within these shared OTUs (white dots). These later percentages apply to the pair with less pyrotags.

picoplankton, nanoplankton and dissolved DNA, (ii) micro/ mesoplankton and (iii) sediments (Fig. 2). Within the planktonic size fractions, samples from each sampling event grouped together (large grey dots in Fig. 2), regardless of water depth or nucleic acid template (only Naples 2010 did not form a cluster due to the atypical sample 'DCM_picoplankton_DNA'). Planktonic samples from the same site collected at different seasons and years did not cluster together, indicating the significant impact of seasonal community changes. By contrast, sediment samples collected in different periods in Naples or Oslo clustered together, suggesting a more stable community in sediments than in plankton.

Protist community structure derived from DNA or RNA extracts exhibited only minor differences. In total, 24 of the 41 DNA/RNA pairs appeared closest in the dendrogram (small black dots in Fig. 2). Most of the other pairs were still very close, but their coupling was less tight than that between picoplankton and nanoplankton from the same site, micro/mesoplankton from surface and deep chlorophyll maximum (DCM) or sediment cores from the same site. Only in two cases (the DCM picoplankton in

Naples 2010 and Oslo 2010) the DNA and RNA samples were rather different, although still belonging to the same geographic cluster.

The dendrogram showed a close association of dissolved DNA samples with the picoplankton and nanoplankton from the same water body (Fig. 2). We then analysed the overlap of individual OTUs among size fractions in the planktonic samples that had a complete sequence report of the four fractions in the DNA survey (Fig. 3). Many of the OTUs from dissolved samples (59% on average) were shared with the picoplankton and nanoplankton (alone, combined or together with the micro/mesoplankton). Still, a substantial number of OTUs (35%) remained unique to dissolved samples, whereas only a few (6%) were shared with the micro/ mesoplankton. We then computed the number of pyrotags from dissolved samples within each shared subarea (Fig. 3). Operational taxonomic units shared with the small size fractions explained 89% of pyrotags, while unique OTUs accounted for 8% of pyrotags. Thus, the dissolved DNA composition largely derived from the picoplankton and nanoplankton fractions.

Taxonomic representations derived from DNA and RNA surveys

Relative abundances of taxonomic groups seen in DNA and RNA-based surveys were analysed separately for picoplankton (13 DNA/RNA pairs), nanoplankton (13 pairs), micro/mesoplankton (10 pairs), and sediment (seven pairs) samples (Fig. 4). Within the picoplankton, we focused in the 26 taxonomic groups more abundant (96.4% pyrotags on average; range of 92.1% to 99.2% in the 26 samples). Most were equally represented in DNA and RNA surveys, as shown by their placement near the 1:1 line (Fig. 4A). Two groups, MALV-I and MALV-II, were notably overrepresented in DNA surveys, averaging 15.4% and 19.7% of DNA pyrotags but only 1.8% and 2.0% of RNA pyrotags. Conversely, seven groups were overrepresented in RNA surveys. These RNA-prevalent groups were Prymnesiophyceae (averaged RNA/DNA pyrotag ratio of 7.4), MOCH-2 (6.0), Pelagophyceae (4.6), Telonema (2.6), Choanomonada (2.1), Ciliophora (2.0) and Chrysophyceae (1.6). In the nanoplankton, we identified 23 taxonomic groups that accounted for 97.1% of pyrotags (between 94.7% and 99.6% among samples), and many were equally represented in both surveys (Fig. 4B). As for the picoplankton fraction, MALV-I and MALV-II were prevalent in nanoplankton DNA surveys (9.8% of DNA signal versus 2.3% in RNA), while virtually the same groups were prevalent in RNA surveys: Prymnesiophyceae (RNA/DNA pyrotag ratio of 8.6), MOCH-2 (5.4), Pelagophyceae (5.3), Choanomonada (3.6), Ciliophora (2.9) and Chrysophyceae (3.7). In the

Fig. 2. UPGMA dendrogram based on the Bray-Curtis dissimilarity matrix from an OTU table with 92 samples (subsampled to 1402 pyrotags and log-transformed). Sample names have four components: sampling cruise, depth, size fraction and nucleic acid template. The three main clusters are highlighted. Large grey dots indicate grouping of samples from the same sampling event, while small black dots indicate a closest relation of the same assemblage analysed by DNA and RNA.

Fig. 3. Number of shared OTUs among plankton size fractions derived from the DNA survey in five cases. Areas covering the dissolved samples are shaded. Below the number of shared OTUs, the percentages of pyrotags they represent in dissolved samples are shown.

Fig. 4. Relative pyrotag abundance in RNA and DNA surveys of taxonomic groups in picoplankton (A), nanoplankton (B), micro/mesoplankton (C) and sediment (D) samples. Each point represents paired percentages (in logarithmic scales) of a given taxonomic group in a given sample. Groups selected are those with highest pyrotag abundance (together account for 96-98% of pyrotags). Groups overrepresented in DNA surveys appear above the 1:1 line as coloured triangles, those over-represented in RNA surveys appear below the line as coloured circles, and those equally represented appear as small black circles.

micro/mesoplankton, nine taxonomic groups explained 98.6% of pyrotags (96.6% to 99.9%). Within this compartment, MALV-I was overrepresented in DNA surveys, and Acantharia showed the opposite trend (Fig. 4C). In sediments, 28 groups accounted for 95.8% of pyrotags (91.4 to 98.4%), and the DNA versus RNA-based taxonomic abundances were more biased than in pelagic samples (Fig. 4D). Seven groups were more abundant in DNA surveys (Apicomplexa, basal Fungi, Dinophyceae, MALV-I, MALV-II, Peronosporomycetes and RAD-B), while four were more abundant in RNA surveys (Bicosoecida, Chrysophyceae, Ciliophora and Tubulinea). In general, taxonomic groups exhibited a consistent RNA/ DNA trend across the four major compartments analysed. An overview of marine coastal protist diversity based on total RNA extracts

We averaged the contribution of each taxonomic group for all samples within the nine different combinations of planktonic size fractions, sediments and nucleic acid templates (Fig. S1). Here, we used the RNA survey to provide an overview of protist diversity within the different ecological compartments (Fig. 5), based on the 40 most prevalent taxonomic groups (which account for 97.7% pyrotags in picoplankton, 98.5% in nanoplankton, 99.4% in micro/mesoplankton and 95.2% in sediment samples). Within the picoplankton, Dinophyceae (25.3%), Ciliophora (11.9%) and Mamiellophyceae (9.3%) were the most

Fig. 5. Percentages of pyrotags (average and standard error) of taxonomic groups in RNA surveys in the picoplankton (13 samples), nanoplankton (13 samples), micro/mesoplankton (11 samples) and sediments (seven samples). Note the different vertical scale in the four plots. Groups are ordered by their overall pyrotag abundance in the whole dataset.

abundant, followed by 19 additional groups with 1% to 8% relative abundance. The taxonomic composition of the nanoplankton was similar to that of the picoplankton, being dominated by Dinophyceae (39.3%), Diatomea (24.9%) and 13 additional groups at 1-8% abundance. Some contributed similarly in both size fractions, but others were clearly overrepresented in the picoplankton (Mamiellophyceae, Chrysophyceae, Pelagophyceae. Picozoa, Chlorarachniophyta, MAST-7 and MAST-4) or in the nanoplankton (Diatomea, Telonema, Katablepharidae and Trebouxiophyceae). The micro/mesoplankton was dominated by Acantharia (35.1%), Dinophyceae (28.9%) and Diatomea (22.4%), and only Ciliophora and MALV-IV displayed 1-8% abundance. Finally, sediments showed remarkable differences with the plankton. Diatomea (40.9%). Ciliophora (19.4%) and Monadofilosa (11.8%) were dominant in these samples, whereas eight additional groups appeared at 1-8% abundances, seven of them being very rare in the plankton: basal Fungi, Labyrinthulomycetes, MAST-6, Granofilosea, Apusomonadida, Apicomplexa and Centrohelida.

Dominant OTUs in RNA surveys

All previous analyses were done with OTUs clustered at 97% similarity, which sometimes enclose more than one species or genera. In our dataset, this was obvious within Dinophyceae (the most abundant OTU97 retrieved 44 genera above 97% similarity), Diatomea and Cryptomonadales. Consequently, we used OTUs clustered at 99% similarity (a total of 63 365 OTU₉₉) to report the dominant taxa (>0.8% of pyrotags) from the RNA survey (Table 2). Dominant OTU99 were often 100% similar to described species. Picoplankton samples were the most distinct, containing small-sized genera like Micromonas, Pelagomonas, Florenciella and Minorisa and several MAST and MALV phytotypes. They also included species within the Acantharia, Ciliophora and Dinophyceae known to belong to the microplankton, so their detection could be due to the presence of small life cycle stages or to filtration artefacts. Dominant OTU99 within the other ecological compartments belonged mostly to Diatomea, Dinophyceae, Ciliophora and Acantharia. Of particular interest were the MALV-IV OTUs in the micro/mesoplankton (MALV-IV are crustaceans' parasites) and OTUs of uncultured basal Fungi, MAST-6 and Monadofilosa in sediments.

Picoplanktonic dominant OTU99 tended to exhibit a high frequency across the investigated sites (Table 2). On average they occurred in 74% of the sites, while the occurrence of dominant OTUs in the other compartments was lower, with an average 65% of sites in the nanoplankton, 56% in the micro/mesoplankton and only 55% in sediments. On note, while the dominant OTU99 of Ciliophora, Acantharia and Diatomea generally appeared in half of the samples, those of Dinophyceae were generally more widespread (86% of sites).

Discussion

Molecular surveys of marine protist diversity initiated in 2001 (Díez et al., 2001; López-García et al., 2001; Moon-van der Staay et al., 2001), and developed together with the availability of new molecular tools including HTS (Amaral-Zettler et al., 2009; Cheung et al., 2010; Edgcomb et al., 2011; Logares et al., 2014). Previous surveys were partial, restricted to a cell-size fraction, a given geographic area or a single nucleic acid template. We study here planktonic and benthic protist diversity inhabiting distant coastal places, from the smallest picoeukaryotes to larger colonial cells up to 2 mm in size (including also dissolved DNA), and derived from DNA and RNA templates. Given that the sampling plan was designed to maximize the ecological space covered, the emerging patterns are likely generalizable to other similar coastal locations (in terms of latitude and/or bathymetry). Seasonal studies at each site, required for a complete diversity description (Nolte et al., 2010), were not addressed in our survey, but time-series HTS datasets are underway in most sites. Moreover, HTS studies using group-specific primers are being conducted to obtain a finer phylogenetic resolution of particular taxonomic groups (Egge et al., 2015). Altogether, our study gives an improved view of marine protists diversity and clearly illustrates the differences between the taxonomic composition derived in DNA and RNA surveys.

Technical considerations

There has been concern about the lack of replication in molecular surveys (Prosser, 2010; Robasky et al., 2014), and our strategy was to test the reproducibility of OTU profiles in a set of 25 samples processed twice for the PCR and pyrosequencing steps. Duplicated pairs were usually very similar (range of R2 from 0.64 to 1.00) and systematically retrieved the same dominant OTUs at comparable relative abundances. Thus, our molecular surveys were well suited for obtaining robust beta-diversity and taxonomic descriptions. Nevertheless, many low abundant OTUs were found in only one pair, implying that undersampling was affecting the richness observed and/or the finding of different errors in each pair (Decelle et al., 2014).

During the preparation of the OTU table for downstream analysis, we removed unknown OTUs that contributed substantially to the OTU number (~13%) but little to the pyrotag number (~1%). This removed sequencing artefacts and chimeras while did not compromise our goal of

Table 2. Averaged relative abundance (% tags), occurrence (number of times detected) and taxonomic affiliation of the most abundant OTU $_{99}$ derived from the RNA survey in the four ecological compartments. Relative abundances in the other compartments (Pic = picoplankton; Nan = nanoplankton: Mic = micro/mesoplankton; Sed = sediments) are also shown.

a comprehensive protist description since they represented few pyrotags. Novel diversity was likely removed; however, investigating novel branches on the tree of life was not the aim of this study and deserves a separate analysis. We also removed OTUs affiliating to metazoans, which contributed 1-10% of pyrotags in picoplankton and nanoplankton and about 50% in micro/mesoplankton and sediment samples. The presence of metazoans in smaller fractions could be due to minute life cycle stages but also to the breakdown of animals during filtration. The later certainly occurs in some cases, such as picoplankton OTUs affiliating to copepods (these have internal fecundation and never release gametes). So, although metazoans are worthy targets for molecular studies (Fonseca et al., 2010), we preferred to exclude them from our analysis. Finally, our survey aimed to cover all eukaryotic lineages but it is important to keep in mind that universal primers may miss some relevant taxonomic groups. In our case, this negative selection was certain for Foraminifera, Prymnesiophyceae and several excavate lineages.

DNA versus RNA-based surveys of total marine protist diversity

Comparing diversity surveys using environmental DNA or RNA is a common practice in microbial ecology (Weinbauer et al., 2002). Initially, the rDNA/rRNA ratios measured from a given microbial population were proposed as proxies of in situ growth rates (Poulsen et al., 1993), but soon this moved to a more qualitative scenario where OTUs found in DNA surveys indicated species present, while OTUs found in RNA represented active species (Stoeck et al., 2007; Jones and Lennon, 2010). Even this simplified view might not be universal, and differences in life histories, life strategies and non-growth activities among species might confound this interpretation (Blazewicz et al., 2013). Nevertheless, protistologists have generally accepted this scenario, and RNA surveys were recently used to identify the active protist community (Stoeck et al., 2007; Not et al., 2009; Lejzerowicz et al., 2013). However, there is an additional factor that may severely affect rDNA/rRNA comparisons in eukaryotes, which is the large variation (up to orders of magnitude) in the rDNA copy number among species (Zhu et al., 2005; Weber and Pawlowski, 2013).

In our dataset, community structure derived from DNA or RNA templates was similar, as paired samples clustered very close in the dendrogram and many taxonomic groups exhibited similar relative abundances. Among the groups with differential abundance, the most extreme were MALV-I and MALV-II that dominated picoplankton DNA surveys as in other studies (Massana, 2011) and contributed little to RNA surveys. One explanation for this discrepancy is that the MALV I-II parasites are abundant in the picoplankton as dispersal, relatively inactive stages with few ribosomes. However, fluorescence in situ hybridization (FISH) direct cell counts showed relative abundances much lower than in DNA surveys (Siano et al., 2010), so a most plausible explanation is that MALV I-II cells have a higher genomic rDNA copy number than other picoeukaryotes. Similarly, groups more abundant in RNA surveys may have lower rDNA copy numbers. Given the consistent trends found across size fractions, our DNA/RNA ratios could reflect different genomic architectures among taxonomic groups, and not necessarily different relative activities. At any rate. RNA surveys should provide a better representation of in situ protist biomass and diversity, since labile RNA likely derives from living cells, in contrast with DNA that can be preserved in dead cells or in the dissolved extracellular pool (Karl and Bailiff, 2012). Our analysis of the eukaryotic diversity derived from dissolved DNA samples showed that, in contrast to what was found in anoxic deep sea sediments (Corinaldesi et al., 2011), these samples did not contain a particular phylogenetic signature. Dissolved DNA samples from these coastal sites resembled the picoplankton and nanoplankton from the same seawater, suggesting cell breakage during filtration.

Marine protist diversity across organismal size fractions and habitats

Our analysis confirms a well-known observation that planktonic and benthic protists are different (Lee and Patterson, 1998; Bik et al., 2012). This was evident in the betadiversity analysis as well as in the taxonomic list, where 13 out of 40 groups were much more abundant in sediments than in the water column. Sediments have also been considered seed banks of planktonic biodiversity, out of which taxa can re-emerge into the plankton at appropriate seasons (Satta et al., 2010). Our data are consistent with this view, since dominant OTUs in the plankton generally were also found, at lower abundances, in sediments.

Regarding planktonic assemblages, our data show a broad differentiation among larger (micro/mesoplankton) and smaller (picoplankton and nanoplankton) protists. This could be due partly to the different collection protocols (net tows and pressure filtration, respectively), but also from the known different cell size of given species. Within the micro/mesoplankton, only four taxonomic groups dominated; Acantharia, Dinophyceae, Diatomea and Ciliophora, and we did not find other relevant groups, consistent with classical inverted microscopy inspections of the plankton. At the other end of the size spectrum, many taxonomic groups were identified, highlighting the high-rank diversity of small marine protists (Massana, 2011). Picoplankton and nanoplankton assemblages from the same seawater were always related, but a closer inspection revealed marked differences in the relative

abundances of key groups. The diversity of both large and small protists was very different in each coastal site, so a standard protist community could not be delineated. Samples from the same site but different seasons were also unrelated, indicating the impact of seasonal successions and highlighting that one or few samples cannot represent the complete diversity at one site.

Molecular surveys of protist diversity have often used size-fractionated samples to discern among different size classes. This step may introduce artefacts, derived from cell breakage and retention of smaller fragments in the smaller size fraction, or from the retention of smaller cells in filters whose larger pores have been obstructed after processing large sample volumes. Our study has ample evidences of the first case, since about 40% of picoplankton pyrotags comes from the four dominating micro/mesoplankton groups. Although part of this signal might derive from gametes or spores (Amato et al., 2007; Kimoto et al., 2011), the most plausible explanation is that larger cells from these groups (typically $>10 \mu m$) are broken during the filtration (Sørensen et al., 2013). This bias could have been even more dramatic had we used a smaller pore-size filter (such as 0.2 µm) for picoplankton collection (Sørensen et al., 2013). Picoeukaryote diversity excluding this microplanktonic signal would be composed by a set of photosynthetic groups (58% of pyrotags), heterotrophic groups (16%), MALV clades (15%) and MAST clades (11%). Following this reasoning, it is expected that nanoplanktonic cells are also represented in the picoplankton (such as Cryptomonadales). The second case of filtration artefact, smaller cells retained in larger size fractions, is not obvious from our data, and groups known to be picoeukaryotes (like Mamiellophyceae, MAST-4 or MAST-7) are only minority in the nanoplankton. So, our data show clear evidence of larger cells collected in smaller size fractions but little support of the other way around. Filtration artefacts need to be considered when interpreting molecular surveys. and cell sizes should be established by direct cell observations by FISH (Siano et al., 2010; Massana, 2011).

Concluding remarks

This study presents a description of marine coastal protist diversity obtained from 95 independent HTS samples. Our data show that larger protists affiliate to a few taxonomic groups well studied by microscopy for decades, whereas smaller protists, known as 'small flagellates', include a wide variety of less-known taxonomic groups. Our results provide answers to the initial questions, with a special emphasis on (i) the general similarity between DNA and RNA surveys despite clear biases in few groups, (ii) the taxonomic discontinuity between micro/mesoplankton and the two smaller size fractions, (iii) the phylogenetic signa-

ture of dissolved DNA deriving from the smallest cells in the sample and (iv) the distinct composition of planktonic and benthic communities. Our data also suggests a higher seasonal variability in the plankton compared with the benthos. These patterns emerging from the large spatial sampling strategy adopted here would likely apply to other coastal sites, while open ocean assemblages require similar approaches (de Vargas *et al.*, 2015). In the future, diversity studies based on sequencing surveys, complementary FISH counts and single amplified genomes analyses will contribute to infer the genetic potential and ecological roles of the key protist players.

Experimental procedures

Sampling

Marine samples were collected through the BioMarKs project (http://biomarks.eu/) in coastal sites near Blanes (Balearic Sea, Spain), Gijon (Gulf of Biscay, Spain), Naples (Tyrrhenian Sea, Italy), Oslo (Skagerrak, Oslofjorden, Norway), Roscoff (Western English Channel, France) and Varna (Black Sea, Bulgaria) (Table 1). Some sites are long-term observatories, the Blanes Bay Microbial Observatory (BBMO), the Long Term Ecological Research station MareChiara (Naples) and the SOMLIT-Astan site (Roscoff). Seawater temperature, salinity and chlorophyll a concentration were recorded with conductivity-temperature-depth and fluorometer sensors. Water samples were collected with Niskin bottles at the sea surface in all sites (and at the DCM in a few sites), and passed through a 20 µm metallic sieve. The nanoplankton (3-20 μm) and picoplankton (0.8-3 μm) fractions were sampled from ~20 litres of seawater filtered sequentially with a peristaltic pump through 3 μm and 0.8 μm polycarbonate (PC) membranes (142 mm diameter) for less than 40 min to minimize RNA degradation. For dissolved DNA, 20 litres of $0.2\,\mu\text{m}\text{-filtered}$ seawater were mixed with 400 ml of 0.5%CTAB (cetyltrimethylammonium bromide) (pH = 8) for 5 h and filtered onto 0.2 µm PC membranes (142 mm). A plankton net of 20 µm mesh size was towed for 5-15 min, and the large protists collected were rinsed with 0.2 µm filtered seawater, passed through a 2000 µm metallic sieve and filtered on 12 µm PC membranes (47 mm), to collect the micro- (20-200 μm) and meso- (200-2000 μm) planktonic fractions (micro/mesoplankton). Filters were flash frozen and stored at -80°C until processed. Finally, sediment cores were taken with a multi-corer sampler or by scuba divers and kept at -80°C until processed.

Nucleic acid extraction and pyrosequencing

Total DNA and RNA were extracted simultaneously from a complete filter using the NucleoSpin RNA kit (Macherey-Nagel) or from 2.5 g of surface sediment (~1 cm upper layer) using the Power Soil RNA kit (MoBio). Extracts were quantified using a Nanodrop ND-1000 Spectrophotometer and checked on a 1.5% agarose gel. Contaminating DNA was removed from RNA extracts using the Turbo DNA-free kit (Ambion). Complete DNA removal was verified by PCR using

eukarvotic primers, and in the few cases of positive PCR, we did a second DNase treatment. One hundred nanograms of extracted RNA were immediately reverse transcribed to complementary (c)DNA using the RT Superscript III random primers kit (Invitrogen). Both DNA extracts and cDNA products were kept at -80°C until processed.

Environmental DNA or cDNA were used as templates for PCR amplification of the V4 region of the 18S rDNA (~380 bp) using primers TAReuk454FWD1 and TAReukREV3 (Stoeck et al., 2010) that amplify most eukaryotic groups. The forward primer had a bar code, and both primers were adapted for 454 sequencing. PCR reactions (25 µl) contained 1x Master Mix Phusion High-Fidelity DNA Polymerase (Finnzymes), 0.35 μM of each primer, 3% dimethylsulphoxide and 5 ng of DNA or cDNA. The PCR program had an initial denaturation step at 98°C during 30 s, 10 cycles of 10 s at 98°C, 30 s at 53°C and 30 s at 72°C, then 15 similar cycles but with 48°C annealing temperature, and a final step at 72°C for 10 min. Polymerase chain reaction triplicates were purified and eluted (30 µl) with NucleoSpin Gel and PCR Clean-Up kit (Macherey-Nagel), and quantified with the Quant-It PicoGreen double stranded DNA Assay kit (Invitrogen). About 1 µg of pooled amplicons were sent to Genoscope (http://www.genoscope.cns.fr, France) for pyrosequencing on a 454 GS FLX Titanium system (454 Life Sciences, USA). The complete sequencing dataset is available at the European Nucleotide Archive under the study accession number PRJEB9133 (http://www.ebi.ac.uk/ena/ data/view/PRJEB9133).

Pyrotag processing and OTU tables

Sequences obtained through 454 sequencing (pyrotags) were de-multiplexed using the bar code identifier in the forward primer. Pyrotags 150-600 bp long with exact primer sequences and homopolymers no longer than eight bases were retained. Identical pyrotags within each sample were de-replicated to keep a single representative sequence. For quality check, errors were computed in sliding windows of 50 bp and pyrotags containing a window with an error >1% and appearing only once in the dataset were removed. Chimera check was run with UCHIME (Edgar et al., 2011), using de novo and reference-based chimera searches against the SILVA108 release (Quast et al., 2013). Additional chimera searches were done using CHIMERASLAYER (Haas et al., 2011) and SILVA108. A local BLAST search (Altschul et al., 1990) against SILVA108 was used to exclude 16S rDNA prokaryotic or plastidial sequences.

This initial procedure yielded ~1.3 million curated pyrotags derived from 120 samples [95 distinct samples, 25 of them in duplicate (same nucleic acid extract but separate PCR and sequencing reactions)]. These were clustered into OTUs at 97% similarity (OTU₉₇) with USEARCH (Edgar, 2010). A local BLAST was done to compare the representative sequence of each OTU (the most abundant one) against the GenBank Release 183.0. Distant OTUs having an e-value $> 10^{-100}$ (below ~85% similarity) were considered as 'unknown' and removed. Taxonomic OTU assignation was performed by best hit BLAST against two reference databases, PR2 (Guillou et al., 2013) and a smaller and phylogenetically fully validated database (Pernice et al., 2013). Metazoans and nucleomorphs were removed, leaving OTUs classified into 99 eukaryotic groups,

including 64 described groups generally at class level (Adl et al., 2012), 27 environmental ribogroups (Guillou et al., 2008; Massana et al., 2014) and eight unidentified categories within each supergroup. The initial OTU table (120 samples) was used to extract duplicated samples. A second table with the distinct 95 samples was prepared for the general diversity analyses. A third table (only the 44 RNA samples) was used for the taxonomic description (see Table S2 for the number of OTUs and pyrotags within these tables).

For beta-diversity analyses, three samples with 300-500 pyrotags (Table S1) were removed from the OTU table, and the remaining 92 samples were subsampled to 1402 pyrotags using the tool 'rrarefy' of the VEGAN R package (Oksanen et al., 2008). Pyrotag counts were log transformed to diminish the effect of the most abundant OTUs, and the table subsampled again with rrarefy (after multiplying the log-transformed values times 1000) to obtain the same signal per sample. A distance matrix was computed with the Bray-Curtis index, and a dendrogram was constructed using the unweighted pair group method with arithmetic mean (UPGMA) function in Vegan. Venn diagrams were generated with the R package VENN DIAGRAM.

Supporting information

Additional Supporting Information may be found in the online version of this article at the publisher's web-site:

- Fig. S1. Percentages of pyrotags (average and standard error) of taxonomic groups in RNA and DNA surveys in the picoplankton, nanoplankton, micro/mesoplankton, sediments and the dissolved fraction (the latter only DNA survey). Note the different vertical scale in the four plots. Groups are ordered by their overall pyrotag abundance in the whole dataset.
- Table S1. Number of pyrotags per 454 sample in the global survey of protist diversity in the plankton (several organismal size fractions) and sediments analysed in DNA and RNA surveys (total of 95 samples). See Table 1 for additional information on sampling cruises.
- Table S2. Number of OTUs and pyrotags included in OTU97 tables, showing the initial numbers and the final numbers after excluding unknown, metazoan and nucleomorph OTUs. Three OTU tables are used in this study: 120 samples (all datasets including duplicates), 95 samples (duplicates removed) and 44 samples (only the RNA survey).
